Endothelial Progenitor Cells Control the Angiogenic Switch in Mouse Lung Metastasis

Dingcheng Gao, Daniel J. Nolan, Albert S. Mellick, Kathryn Bambino, Kevin McDonnell, Vivek Mittal*

Angiogenesis-mediated progression of micrometastasis to lethal macrometastasis is the major cause of death in cancer patients. Here, using mouse models of pulmonary metastasis, we identify bone marrow (BM)–derived endothelial progenitor cells (EPCs) as critical regulators of this angiogenic switch. We show that tumors induce expression of the transcription factor Id1 in the EPCs and that suppression of Id1 after metastatic colonization blocked EPC mobilization, caused angiogenesis inhibition, impaired pulmonary macrometastases, and increased survival of tumor-bearing animals. These findings establish the role of EPCs in metastatic progression in preclinical models and suggest that selective targeting of EPCs may merit investigation as a therapy for cancer patients with lung metastases.

Disseminated malignant primary tumor cells colonize target secondary organs, through bone marrow (BM)–derived premetastatic niches (I, 2), to form dormant micrometastases (3). In some cases, these micrometastases activate the angiogenic switch and progress to macrometastases (4, 5). The cellular and molecular mechanisms regulating the angiogenic switch and the dynamics of vessel assembly during the progression of micrometastases to macrometastases remain poorly understood, which limits the utility of antiangiogenic approaches to controlling metastasis. In this study, we have investigated whether BM-derived endothelial progenitor cells (EPCs) contribute to angiogenesis-mediated progression of micrometastases into deadly macrometastases.

To facilitate tracking of both metastatic tumor cells and BM-derived cells in vivo, we implanted Lewis lung carcinoma cells stably expressing red fluorescent protein (LLC-RFP) into syngeneic mice reconstituted with BM cells expressing green fluorescent protein (GFP+) BM (fig. S1A) (6). After primary tumor resection (fig. S1B), numerous GFP+ pulmonary micrometastases (<1 mm in diameter) were detected by stereomicroscopic imaging at day 14 after tumor inoculation (12 on average per animal) (fig. S1C). The total number of metastases increased with time (average 22 and 35 per animal at day 21 and day 28, respectively) (Fig. 1A), with a concomitant increase in macrometastases (≥1 mm in diameter, 47% at day 28) (Fig. 1A), which indicated a time window of micrometastasis to macrometastasis progression. We next determined whether this window of metastasis progression was associated with the angiogenic switch. Immunohistochemical staining showed that the micrometastatic foci (day 14) were largely avascular, as determined by a lack of CD31+ vessels (Fig. 1B, top). In contrast, macrometastatic foci (days 21 to 28) were infiltrated with many CD31+ vessels of various sizes (Fig. 1B, bottom), which suggested that these lesions had undergone an angiogenic switch during their expansion in size. As expected, many BM-derived GFP+ cells were recruited to both micro- and macro-metastases (fig. S1C and Fig. 1B). Although a majority of these cells represented hematopoietic lineages, as previously described in primary tumors (7) (fig. S2A), we focused on BM-derived endothelial cells that directly contribute to neovascularization (8). Microscopic analysis of macrometastases showed that a subset of neovessels had incorporated BM-derived endothelial cells [GFP+CD31+ (Fig. 1C)]. Luminoral incorporation was confirmed by optical sectioning microscopy, which showed that the GFP and CD31 signals were localized to the same individual cell in all three dimensions [supporting online material (SOM) text, Note 1, and (fig. S2B)]. Functional incorporation of BM-derived endothelial cells was quantified by systemic perfusion of fluorescently labeled isocitrate GS-B4, which specifically binds to the luminal surface of endothelial cells in vessels with active blood circulation (8, 9). Macrometastases were dissected from the lungs, and fluorescence activated cell sorting (FACS) analysis showed that the luminaally incorporated BM-derived endothelial cells (GFP Lectin CD31+CD11b−) represented on average 12.7 ± 2.9% of total endothelial cells (Lectin CD31+CD11b−) (Fig. 1, D and E).

To confirm that these events also occur in a model of spontaneous metastasis, we transplanted syngeneic GFP+ BM into MMTV-PyMT transgenic mice, a model of breast cancer. Pulmonary micrometastases were detected in the mice at 12 weeks of age, and these lesions progressed into numerous macrometastases by week 16 (Fig. 2A). Notably, GFP+ BM-derived cells colocalized with the metastatic lesions (Fig. 2B). As observed in the LLC model, the micrometastases were avascular and lacked CD31+ vessels (Fig. 2C), whereas macrometastases were infiltrated by CD31+ neovessels (Fig. 2D), which indicated that these lesions had undergone an angiogenic switch at this defined window. Histology revealed vessel-incorporated GFP+ CD31+ BM-derived endothelial cells (Fig. 2E). Further quantification showed that 11.7 ± 3.7% of vessels in the metastases contained incorporated GFP+ BM-derived endothelial cells (Fig. 2F).

We have previously shown that the BM-derived endothelial cells are derived from progenitor cells defined by cell surface expression of vascular endothelial (VE)–cadherin, vascular endothelial growth factor receptor 2 (VEGFR2), dim CD31, and Prominin I and lack various hematopoietic markers (8). Analysis of micrometastases showed infiltration of BM-derived GFP+ VE-cadherin+ EPCs in the peripheral region of the lesions (Fig. 3A). FACS analysis of the lungs bearing micro-
metastases showed a fivefold increase in BM-derived EPCs (GFP+ VE-cadherin+ CD31dim CD11b−), as compared with that of control normal lungs (198.5 ± 29.9 versus 37.3 ± 6.1, P < 0.0001) (Fig. 3, B and C). To determine the mechanism underlying EPC recruitment to the sites of neovascularization, we examined metastatic lesions for the expression of adhesion molecules. Nascent vessels confined to the metastatic lesions expressed higher levels of vascular cell adhesion molecule-1 (VCAM-1), and notably, EPCs expressed cognate receptors integrin α4β1 (fig. S3, A, C, and D). Indeed, the presence of EPCs in the proximity of VCAM-1+ vessels (fig. S3B) suggests that interactions between VCAM-1 and integrin α4β1 mediate EPC recruitment, as observed previously for hematopoietic progenitors (10–12). Taken together, these results demonstrate that an angiogenic switch is associated with the progression of micrometastases to macrometastases, during which BM-derived EPCs are recruited to the metastatic foci and contribute luminally to the neovasculature in metastatic lesions.

To explore whether BM-derived EPCs are required for the progression of micrometastasis to macrometastasis, we studied the effects of loss of EPC function in vivo. We focused on the Id1 transcription factor because Id1 knockout mice (Id1+/−Id3−/−) exhibit impaired tumor growth, because of BM-associated angiogenic defects (13, 14). Notably, in response to a tumor challenge, we detected a ~2.5-fold up-regulation in Id1 mRNA expression in the BM cells (Fig. 3D). More important, Id1 expression was confined to EPCs and was not seen in other BM cells upon tumor challenge (Fig. 3E and fig. S4A), which suggests that Id1 may be critical for EPC function in the context of metastasis. To dissect the role of Id1 in EPC-mediated progression of metastatic lesions, we used a lentiviral-based synthetic microRNA (miR-30)–based short hairpin RNA (shRNA) expression system whose activity could be induced by doxycycline (Dox) to target Id1 expression in vivo (fig. S5). This approach allowed us to generate acute Id1 suppression in the BM selectively during metastasis progression without compromising the contribution of BM-derived endothelial cells to the growth of primary tumor, which cannot be achieved in the Id1 knockout models.
mice. An effective shRNA that reduced endogenous Id1 mRNA and protein levels (>95% reduction) (fig. S4, B and C) was cloned into a Dox–inducible expression vector (fig. S4D). The specific and tight regulation of Id1 shRNA expression by the inducible system was established in the context of genomic integration in vitro (fig. S4, E and F).

To determine the impact of Id1 gene suppression on metastasis progression, lineage negative (Lin−) cells derived from ROSA26 reverse tetracycline transactivator (rtTA) transgenic mice (15) were transduced ex vivo with lentivirus expressing either the Id1 shRNA or the nonspecific shRNA and transplanted into lethally irradiated recipient mice according to the scheme in fig. S5A. No significant change in primary tumor growth was observed in these animals (fig. S5B) before Dox administration. However, Dox-mediated induction of Id1 shRNA expression substantially reduced the total number of metastases in animals having an Id1 shRNA bone marrow transplant (BMT) (28 ± 6 in –Dox versus 8 ± 5 in +Dox) as compared with nonspecific shRNA-
BMT animals [32 ± 7 in −Dox versus 33 ± 6 in +Dox (Fig. 4A)]. This reduction was due primarily to a decrease in macroemetastases in Dox-treated Id1 shRNA–BMT animals [13.8 ± 6.1 in −Dox versus 0.6 ± 1.3 in +Dox, *P* = 0.0014 (Fig. 4B)]. No significant reduction in micrometastases was observed in the lungs of these animals (Fig. 4C), which suggested that the inducible Id1 suppression did not affect initial lung colonization by tumor cells, but impaired their progression into macrometastases. Furthermore, tumor-bearing Id1 shRNA–BMT mice treated with Dox outlived the untreated mice (*P* = 0.0233 (Fig. 4D)). Necropsy revealed that the untreated mice had collapsed lungs containing numerous macroemetastatic lesions (Fig. 4D, insert −Dox), which suggested that pulmonary macroemetastasis was the main cause of death.

Inducible suppression of Id1 gene expression in vivo was confirmed by quantitative real-time polymerase chain reaction (RT-PCR), which showed a reduction in Id1 mRNA levels in the BM of the Dox-treated Id1 shRNA–BMT mice to one-fifth those of untreated mice (Fig. 4E). More important, conditional Id1 suppression resulted in reduction in the level of circulating EPCs (c-kit−VEGFR2−CD11b−) to one-third the circulating EPCs in those without doxycycline (Fig. 4F). The reduction in EPCs was specific, as we detected no significant change in the levels of BM-derived hematopoietic cells, including B cells, T cells, and myeloid and VEGFR1+ cells (Figs. S6 to S8). Our data also suggest that a decrease in lymphocyte in resting Id1 knockout mice recently reported by Nimer and colleagues (16) was most likely due to developmental compensation associated with the knockout mice. Overall, our study provides evidence that BM-derived EPCs play a direct role in angiogenesis-mediated progression of metastatic lesions, but they have no effect on metastatic initiation, which is dependent on VEGFR1+ cells. Notably, impaired mobilization of EPCs resulted in a dramatic reduction in vessel density in metastatic lesions in Dox-treated Id1 shRNA–BMT mice [22.2 ± 4.7% in −Dox versus 4.1 ± 2.9% in +Dox (Fig. 4G)]. Although we have observed that a reduction in the levels of circulating EPCs correlates with impaired angiogenesis, our study does not address whether local lung resident progenitors or dedifferentiation of committed hematopoietic cells also contribute to EPC population as reviewed in (17).

This study illustrates the critical role of EPCs as novel regulators of the angiogenic switch in metastatic progression and points to a direct role of Id1 in mediating EPC mobilization and recruitment. Although only 12% of the neovessels in the metastatic lesions showed luminal incorporation by BM-derived endothelial cells, it is noteworthy that blocking EPC mobilization caused severe angiogenesis inhibition and significantly impaired the formation of lethal macrometastases, which suggested that EPCs may have additional antiangiogenic properties in mediating the angiogenic switch. Notably, gene expression analysis of FACS-purified EPCs from tumor tissue revealed up-regulation of a variety of key proangiogenic genes including growth factors, receptors, chemokines, and ECM modifiers (table S1). Together, these findings support the rationale for the antiangiogenic treatment of metastatic cancer and suggest that the efficacy of antiangiogenic inhibitors currently used in clinical trials, such as blocking antibodies to VEGF and VEGFR2, may be a consequence of directly targeting BM-derived EPCs, as well as the nascent tumor vasculature. This hypothesis is bolstered by studies that have shown that antiangiogenic drugs also suppress the mobilization and levels of EPCs (18). Given that BM-derived endothelial cells also contribute to vessels in humans (19, 20) and that initial metastatic colonization has usually occurred by the time of the primary tumor diagnosis, our results suggest that targeting BM-derived EPCs, perhaps in combination with conventional chemotherapeutics, may provide a feasible therapeutic approach for cancer patients with lung metastases. It is important to note, however, that in the clinical setting it can sometimes take years for dormant micrometastases to progress to lethal micrometastases, a time course that is not recapitulated in our mouse models.

**Dendritic Cell–Induced Memory T Cell Activation in Nonlymphoid Tissues**

Linda M. Wakim,1 Jason Waithman,1 Nico van Rooijen,2 William R. Heath,3 Francis R. Carbone3*

Secondary lymphoid organs are dominant sites of T cell activation, although many T cells are subsequently retained within peripheral tissues. Currently, these nonlymphoid compartments are viewed as sites only of effector T cell function, without the involvement of renewed induction of immunity via the interactions with professional antigen-presenting cells. We describe a method of reactivation of herpes simplex virus to examine the stimulation of tissue-resident T cells during secondary challenge. The results revealed that memory CD8+ T cell responses can be initiated within peripheral tissues through a tripartite interaction that includes CD4+ T cells and recruited dendritic cells. These findings lend evidence for the existence of a sophisticated T cell response mechanism in extra-lymphoid tissues that can act to control localized infection.
